(54) Title: USE OF FRESNEL ZONE PLATES FOR MATERIAL PROCESSING**(57) Abstract**

The apparatus for machining and material processing includes an excimer laser and a Fresnel zone plate array (FZP) positioned parallel to the workpiece, with the distance between the FZP and the workpiece being the focal length of the FZP. For each hole to be formed on the workpiece a corresponding Fresnel zone is patterned onto the FZP. Each Fresnel zone may be patterned directly centered over the desired hole location or in high density patterns it may be located off-center from the hole with deflection being accomplished by the formation of finer circular arcs on the side of the Fresnel zone opposite the desired direction of deflection. A beam scanner is included to provide a more uniform illumination of the FZP by the laser beam. The scanning eliminates non-uniformity of intensity. The alignment mechanism uses a helium-neon laser, the beam from which is projected onto a surface relief grating on the workpiece. The reflected light from the surface relief grating is filtered to create interference fringes which, when aligned, provide maximum light intensity projected through a transmission grating on the Fresnel zone plate.

-1-

USE OF FRESNEL ZONE PLATES FOR MATERIAL PROCESSING

BACKGROUND OF THE INVENTION

5 Very small holes of arbitrary contours are important for many applications, including fabricating vias in printed circuit boards and integrated circuit packages. Traditional mechanical means of forming vias, such as drills or punches, are capable of forming vias as small as 0.004 inch (.10 mm).
10 Below this limit, lithographic or optical techniques must be used.

 One of the optical techniques for micro-machining is direct ablation with a laser focused onto the workpiece with a microscope. Vias are drilled one-at-a-time with the stage
15 on which the workpiece sits scanning to the next via to be formed, repeating the procedure until all of the vias are formed. This technique may include the use of a patterned metal mask over the surface of the substrate so that the laser ablates material only through the openings in the metal.
20 After ablation the metal can be patterned or removed as the design requires. The processing quality of this method is limited in that it takes a relatively long time to complete a single workpiece.

 Lithographic techniques include determining the pattern
25 of vias with photoresist then subjecting the workpiece to reactive ion etch. The photoresist is subsequently removed leaving the vias patterned in the workpiece. The reactive ion etch involves the use of a very expensive piece of equipment, and several additional process steps are required for
30 patterning, etch and photoresist strip.

-2-

It is known that laser machining can be done using modulated zone plates, holographic optical elements and binary phase gratings. These diffractive optics are more efficient than mask-based techniques, theoretically being capable of directing 100% of the incident light into a desired image. However, these diffractive optics techniques are limited in that many of them are only capable of generating a periodic matrix of spots, and they often require a refractive lens for focusing which may reduce efficiency and introduce aberrations and distortion.

It would be desirable to provide an apparatus and method for machining and material processing which provides the efficiency of diffractive optics techniques and a laser while permitting the formation of an arbitrary pattern which may be created for specific applications. It is such an apparatus and method to which the present invention is directed.

SUMMARY OF THE INVENTION

It is an advantage of the present invention to provide a system which uses diffractive optics techniques to form an arbitrary pattern for machining and material processing.

It is a further advantage of the present invention to permit the simultaneous processing of multiple areas within the field of view using approximately parallel beams of uniform power, and without having to step or scan the stage on which the workpiece is mounted.

It is another advantage of the present invention to permit highly accurate alignment of the diffractive optic with the workpiece to assure correct location of the beams.

-3-

In an exemplary embodiment the apparatus for drilling vias or holes in a circuit board includes an excimer laser and a Fresnel zone plate (FZP) positioned parallel to the circuit board, with the distance between the FZP and the circuit board being the focal length of the FZP. For each via to be formed in the circuit board a corresponding FZP is patterned onto an FZP array. Each FZP may be patterned directly centered over the desired via location or in high density patterns it may be located off-center from the via with deflection being accomplished by the formation of finer circular arcs on the side of the FZP opposite the desired direction of deflection.

A beam scanner is included to provide a more uniform illumination of the FZP by the laser beam. The scanning eliminates non-uniformity of intensity.

The alignment mechanism uses a helium-neon laser, the beam from which is projected onto a surface relief grating on the workpiece. The reflected light from the surface relief grating is filtered to create interference fringes which, when aligned, provide maximum light intensity projected through a transmission grating on the Fresnel zone plate.

The FZP may be patterned to provide any contour hole by producing the pattern of the Fourier transform of the desired hole shape.

BRIEF DESCRIPTION OF THE DRAWINGS

Understanding of the present invention will be facilitated by consideration of the following detailed description of a preferred embodiment of the present invention, taken in conjunction with the accompanying

-4-

drawings, in which like reference numerals refer to like parts and in which:

Figure 1 is a diagrammatic view of the material processing system according to the preferred embodiment;

5 Figure 2 illustrates a Fresnel zone plate array;

Figure 3 illustrates Fresnel zone plate configuration to achieve beam tilt;

Figure 4 is a perspective view of the alignment subsystem; and

10 Figure 5 is a perspective view illustrating motion for the beam scanner.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

15 In the preferred embodiment shown in Figure 1, the material processing system comprises a processing laser 2 for emitting beam 3, a beam scanner 4, a spatial filter 5, a beam expander/collimator optical train 6, a Fresnel zone plate array 8 and an alignment subsystem 10. The workpiece, 20 illustrated as a circuit board 12 is mounted on stage 14.

Processing laser 2 is an excimer laser, which provides a single pulse brightness in ultraviolet light much greater than that emitted by other commercial lasers. The preferred excimer laser is KrF which emits at 248 nm and provides a 25 power of 400 mJ/pulse for a 20 nsec pulse. This particular laser is selected for its ability to ablate polyimide which is used for printed circuit boards and alumina (Al_2O_3) which is used in ceramic packaging.

30 Beam scanner 4 is included because the laser beam quality has been tailored to the requirements for focusing the laser to the diameter specifications of a circuit board. The beam

-5-

quality modifications generate a speckle pattern which decreases the uniformity of the laser intensity. Laser uniformity is an important parameter because it affects the diameter of the via. Since the polyimide has an energy
5 threshold below which little ablation occurs, the profile of the laser beam will have the effect that a higher intensity pulse will be wider at the ablation threshold because the tails of the beam profile have increased in intensity. This results in an increase in hole diameter which creates a
10 nonuniform distribution of hole diameters across the circuit board 12, possibly exceeding specified tolerances.

Beam scanner 4 alleviates the nonuniform intensity of the beam by causing the beam to continuously scan across a narrow region such that it overlaps itself at all locations during
15 the scan. The beam scanner 4, shown in Figure 5, consists of two stages 41 and 42 with reflectors 43 and 44. Stage 41 oscillates continuously in $\pm x$ -direction with reflector 43 mounted thereon at a 45° angle. Motion of stage 41 in $\pm x$ -direction causes the beam to move in the $\pm x$ -direction at the
20 target plane while motion of stage 42 in $\pm z$ -direction causes the beam to move in the $\pm z$ direction at the target plane. By appropriately programming the motion of stages 41 and 42, any desired scanning pattern in the target plane can be achieved. Stages 41 and 42 have tight pitch and yaw specifications so
25 that the motion does not introduce any beam tilt.

Spatial filter 5 is a pinhole provided to permit spatial filtering of the input beam. The pinhole rejects highly divergent components of the laser beam.

Beam expander/collimator optical train 6 is illustrated
30 a simple combination of lenses which expand the beam 3 to match the beam size to the workpiece then collimate the

-6-

expanded beam. A more complex multiple lens telescope may also be used for precise magnification and speed, suggested values being 6:1 and $f/20$, respectively.

5 Fresnel zone plates (FZPs) are structures for focusing light that can be readily mass produced in arbitrary arrangements. They therefore provide an effective means for etching patterns of holes using laser light. A single substrate can be imprinted with a large number of FZPs using standard lithographic techniques. The operating principle of
10 FZPs is the diffraction of light. The principle of diffraction states that a lightwave will not travel in a straight path after passing through a small aperture (small meaning comparable in size to the wavelength), but will expand outward to fill the space behind the aperture. Thus, light
15 beams passing through a screen with two or more apertures will overlap and combine. Because light is a wave, it has peaks and troughs in its amplitude. When beams combine, a peak in one beam may be cancelled by a trough in another, leaving that location dark. This is called destructive interference.
20 Likewise, at other locations, beams will combine so that two peaks or two troughs come together. This increases the amplitude of light at those locations and is called constructive interference. A screen with the correct pattern of apertures can be used to focus light. Light at the focus
25 should have as high an amplitude as possible. Therefore, only apertures that contribute constructively interfering light to the focus position should be open in the screen. Whether an aperture contributes constructive or destructive light depends on the distance of the aperture from the focus. If one
30 selects a particular aperture at a given distance from the focus, then all other apertures at that same distance to

-7-

within plus or minus one quarter of a wavelength will contribute constructive light. Furthermore, all apertures within a quarter wavelength of that distance plus or minus an integer number of wavelengths will also contribute constructive light. The pattern that results if all constructive aperture locations on a screen are transparent and all destructive locations are opaque is a series of concentric rings with the spacing of the rings becoming closer for rings further from the center of the pattern. This pattern of rings is an FZP.

The total amplitude of light at the focus can be increased by using the light that would ordinarily be blocked by the opaque rings of the FZP. Destructive light can be turned to constructive light by changing its phase by half a wavelength. Thus, by replacing the opaque rings of the FZP with a thickness of transparent material that delays the light by one half wavelength, those regions can also constructively contribute to the focus, thereby doubling the total light amplitude. Materials etched by light at the focus react not to light amplitude, but to light intensity which is the square of the amplitude. Thus, doubling the amplitude increases the potential for etching by a factor of four.

The procedure for fabricating a Fresnel zone plate involves the preparation of a mask using electron beam lithography. Since E-beam lithography involves directly "writing" the pattern into photoresist on the chrome mask plate, it is relatively little additional work to pattern a large number of zones on a single mask. The location of each zone is determined by the pattern of beam projection desired to simultaneously process selected locations of a workpiece. The perimeter of the FZP array will have a clear unpatterned

-8-

area 7 on the order of 1 cm wide to permit inclusion of alignment features. After etching of the exposed chrome (under the unexposed resist) and stripping of the resist, a mask is created bearing a pattern of the desired FZP array.

5 An example of such a pattern with partially overlapping FZPs is shown in Figure 2. The ability to partially overlap the zones permits relatively close and arbitrary positioning of the selected areas of the workpiece as required. It should also be noted that the FZPs and the selected area on the
10 workpiece corresponding need not be limited to a circular shape. By patterning the FZP as the Fourier transform of the desired shape virtually any shape via or hole can be drilled, including squares, polygons, asymmetric shapes, etc.

The mask is used to pattern photoresist on a quartz plate
15 by projecting light through the mask to expose the resist. After exposure, the quartz is etched using either wet chemical (HF) or reactive ion etch (RIE). Wet etch can be used only where small spacing between the lines on the plate is not critical, because the isotropic nature of the wet etch results
20 in undercut of the resist making dimensions difficult to control. RIE, an anisotropic etch, is preferred and is necessary to achieve narrow spacing between the lines with well-defined vertical steps.

The design of an FZP is as follows: the radius of the
25 k-th circle that separates the rings of the zone is given by $\sqrt{k\lambda f}$, where λ is the wavelength of light emitted by the processing laser 2 and f is the focal length of the Fresnel zone. The total number of bright and dark rings in a Fresnel zone with radius R is $K = R^2/\lambda f$. The width of the narrowest
30 ring, which determines the resolution required for fabrication, is $\sqrt{k\lambda f} - \sqrt{(k-1)\lambda f}$. The etch depth of the

-9-

quartz, which can be achieved by either etch technique, is $L = \lambda/[4(n-1)]$, where n is the refractive index of quartz, about 1.55. Etching precisely to this depth will give the highest optical power at the focused spot.

5 In the preferred embodiment of the system, FZP array 8 is positioned parallel to the circuit board 12, 50 millimeters away. Thus, the focal length of the FZP is 50 mm. The holes drilled in the circuit board 12 are 12.5 microns in diameter. The holes are randomly positioned on the workpiece and may be
10 as close as 75 microns center-to-center. To etch 12.5 micron holes from a distance of 50 mm, the FZPs must be 1 mm in diameter, using zones centered over the holes as seen in Figure 3a. To allow holes to approach to within 75 microns, the FZPs must be able to produce holes that are not centered
15 behind the FZP, but deflected to one side as in Figures 3b and 3c. For a large diameter zone plate, any selected 1 mm square area of that pattern directs light to the focus behind the center of the pattern. Therefore, FZPs designed to produce holes not centered under them will be 1 mm square areas
20 selected from the outer portion of larger FZPs. The more the hole is deflected from the center of the FZP, the finer the circular arcs of the FZP opposite the direction of deflection, as shown in Figure 3c. Thus, the maximum deflection is limited by the minimum resolution of the fabrication process.
25 The pitch L of the arcs is determined according to the relationship $L = \lambda/2\sin\theta$ where θ is the angle of deflection. If features as fine as 0.5 microns can be fabricated, then holes may be placed up to 4.5 mm from the center of the corresponding FZP element. These specifications will allow
30 writing a diagonal line of holes on a 75 micron grid.

-10-

Alignment subsystem 10 is shown in Figure 4. Reference laser 20 emits light within the visible spectrum, for example, a helium-neon laser (632.8 nm). Alignment beam 22 is projected toward a reflective prism 24 attached to the perimeter of FZP 8 which directs beam 22 through a clear area 7 of FZP toward a location on the circuit board 12 at which is patterned a surface relief grating 14. Note that the prism 24 projects beam 22 at a slight angle toward grating 14. This is necessary to permit the reflected beam to pass through a different location than directly back to prism 24. When beam 22 strikes grating 15 it is split into several diffracted orders which are reflected back toward the FZP array through a blocking filter 16 which filters the reflected light, removing all diffracted orders except the -1 and +1. As shown in Figure 4b, visible light beam 22 passes through refractive prism 24 which causes beam 22 to leave Fresnel zone plate array 8 at an angle. Beam 22 strikes surface relief grating 14 on workpiece 12. Grating 14 breaks beam 22 into multiple diffracted orders 23. Diffracted orders 23 are reflected and focused by reflective grating lens 29. Beams 23 reflect a second time off mirrored surface 16, which is patterned to reflect +1 and -1 diffracted beams but to stop 0th and all other beams. The +1 and -1 beams encountered reflective bumps 17 on top surface of 8. Purpose of bumps 17 is that beam 22 may be scanned through small angles, causing +1 and -1 beams to move onto and off of bumps 17. As they do so, their relative phases are modulated. Beams reflect once more off of 16 and from interference pattern at plane of transmission grating 18. Proper alignment of workpiece 12 and plate 8 gives maximum signal to detector 24. Phase modulation of beams produced by bumps 17 serves to rock interference pattern

:

-11-

back and forth, giving a modulated signal to detector 24. This modulated signal is suitable for synchronous detection which gives high accuracy and noise immunity. Mirrored surface 16 may be placed on the underside of FZP array 8 or
5 may be a separate component. The transmission and combination of the -1 and +1 diffracted orders create interference fringes which then pass through transmission grating 18 which is preferably patterned on the perimeter of FZP array 8. Transmission grating 18 may alternately be a separate
10 component. The light passing through the transmission grating 18 is measured at detector 24 to determine the total amount of light passed. By adjusting the rotation tilt and/or lateral movement of the FZP 8 or the stage 14 on which the circuit board 12 is mounted, the maximum intensity of light
15 transmitted through transmission grating 18 is achieved, indicating alignment.

The above alignment procedure is preferably performed at two or more locations which may be facilitated by placing beamsplitter 25 between laser 20 and reflective prism 24 to
20 provide two separate beams 22 and 22' which impact gratings 15 and 15', respectively to permit the above-described alignment procedure at two locations.

In an alternate embodiment alignment subsystem 30, using a reference laser 20 as above, directs a reference beam
25 through a reticle which has a set of alignment marks patterned at two of its edges. A corresponding set of alignment marks is located on the workpiece onto which reference beam is focused by the use of a Fresnel lens. The alignment marks are partially reflective, reflecting the beam back through the
30 reticle and alignment marks thereon. A camera looks at the

-12-

images carried by the reflected beam to determine whether complete overlap and, thus, alignment has been achieved.

The material processing method and system of the present invention permits many locations to be processed
5 simultaneously, providing high system throughput while efficiently using available laser power. The processing steps for producing FZPs by standard lithographic techniques allow arbitrary patterning for customization of plates in accordance with a user's requirements. The alignment subsystem permits
10 repeatable positioning further allowing whole field stepping to increase throughput.

It will be evident that there are additional embodiments which are not illustrated above but which are clearly within the scope and spirit of the present invention. The above
15 description and drawings are therefore intended to be exemplary only and the scope of the invention is to be limited solely by the appended claims.

WE CLAIM:

-13-

CLAIMS

1. An apparatus for processing a workpiece by simultaneously projecting a plurality of beams of equal intensity onto selected areas of said workpiece, one beam corresponding to each selected area, said apparatus comprising:

a light source for generating an incident processing beam having at least one wavefront; and

a Fresnel zone plate array having a plurality of regions and a clear strip at its perimeter, each region of said plurality corresponding to one said selected area, said wavefront impinging upon said Fresnel zone plate array causing one said beam to be projected from each said region, said beam being focused on its corresponding said selected area;

whereby each said beam performs a process at its corresponding said selected area with processing of said workpiece being simultaneously equally and uniformly accomplished.

2. An apparatus as in Claim 1 further comprising a beam scanner for scanning said incident processing beam onto said Fresnel zone plate array to compensate for non-uniformities of intensity of said incident processing beam.

3. An apparatus as in Claim 1 further comprising an alignment mechanism comprising:

a laser for emitting a reference beam of light in the visible spectrum;

-14-

at least one refracting prism disposed within a path
6 of said reference beam for directing said reference beam
through said Fresnel zone plate toward said workpiece;

8 an alignment mark on said workpiece corresponding to
each said refracting prism for reflecting said reference beam
10 along a reflected beam path back toward said Fresnel zone
plate;

12 at least one grating disposed within said reflected
beam path for selectively transmitting said reflected beam;

14 and

a detector for detecting said reflected beam
16 projected through said at least one grating to determine
intensity of light of said reflected beam, said intensity of
18 light being an indicator of alignment.

4. An apparatus as in Claim 3 wherein said reflecting
2 prism is disposed on said clear strip.

5. An apparatus as in Claim 3 wherein said at least one
2 grating is disposed on said clear strip.

6. An apparatus as in Claim 3 wherein said at least one
2 grating comprises a plurality of reflective and transmissive
gratings for selectively reflecting said reflected beam within
4 said clear strip before selectively transmitting said
reflected beam.

7. An apparatus as in Claim 1 further comprising an
2 alignment mechanism comprising:

a laser for emitting a reference beam of light in
4 the visible spectrum;

-15-

6 a reticle having a plurality of first alignment
marks patterned thereon through which said reference beam is
8 projected onto a plurality of second alignment marks
corresponding to said plurality of first alignment marks on
said workpiece, each second alignment mark being at least
10 partially reflective; and

12 a camera for detecting said reference beam after
said reference beam is reflected from said second alignment
mark back through said reticle so that each said first
14 alignment mark and its corresponding said second alignment
mark may be compared to determine alignment.

8. An apparatus as in Claim 1 wherein said Fresnel zone
2 plate array consists of a quartz plate patterned with a
plurality of regions, each region comprising a plurality of
4 ridges and valleys surrounding a center point, each valley
having a depth of $\lambda/4(n-1)$ where λ is the wavelength of light
6 emitted by said light source and n is the refractive index of
said quartz plate.

9. An apparatus as in Claim 1 wherein said Fresnel zone
2 plate array consists of a glass plate patterned with a
plurality of regions, each region comprising a pattern of
4 plurality of ridges and valleys surrounding a center point,
each valley having a depth of $\lambda/4(n-1)$ where λ is the
6 wavelength of light emitted by said light source and n is the
refractive index of said glass plate.

10. An apparatus as in Claims 8 or 9 wherein said
2 pattern comprises the Fourier transform of a shape to be
processed at said selected area.

-16-

11. An apparatus as in Claim 2 wherein said beam scanner
2 includes a plurality of stages with reflectors disposed
thereon for reflecting said incident beam and causing said
4 incident beam to be scanned over a target plane.

12. A method of processing a plurality of selected
2 locations on a workpiece by simultaneously focusing a
plurality of beams of equal intensity onto said workpiece
4 which comprises:

projecting a reference beam of light from a
6 reference laser through a plurality of first alignment marks
on a transparent plate located above said workpiece;

8 aligning said plurality of first alignment marks
with a plurality of second alignment marks on said workpiece;

10 projecting an incident processing beam through a
Fresnel zone plate having a plurality of zones disposed
12 therein, one zone corresponding to each selected location on
said workpiece, thereby creating a plurality of processing
14 beams of equal intensity, one beam corresponding to said each
selected location.

13. A method as in Claim 12 further comprising scanning
2 said incident beam to eliminate beam non-uniformity.
